4 1. Introduction

5 The concept of accessibility in transportation studies derives its appeal from
6 the combination of the spatial distribution of opportunities and the cost of
7 reaching them [21, 19]. Accessibility analysis is employed in transportation,
8 geography, public health, and many other areas, with the number of applications
9 growing [51], especially as mobility-based planning is de-emphasized in favor of
10 access-oriented planning [15, 20, 42, 57].

11 Numerous methods for calculating accessibility have been proposed in the
12 literature [18]. Of these, gravity-type accessibility is arguably the most common;
13 since its introduction in the literature by Hansen [21], it has been widely adopted
14 in numerous forms [10, 39, 18, 31, 3]. Gravity-based accessibility indicators
15 are essentially weighted sums of opportunities, with the weights given by an
16 impedance function that depends on the cost of movement, and thus measure the
17 *intensity of the possibility of interaction* [21]. This type of accessibility analysis
18 offers a powerful tool to study the intersection between urban structure and
19 transportation infrastructure [19].

20 Despite their utility, the interpretability of gravity-type accessibility measures
21 can be challenging [18, 36]. Since they aggregate opportunities, the results are
22 sensitive to the size of the region of interest (e.g., a large city has more jobs than
23 a smaller city). As a consequence, raw outputs are not necessarily comparable
24 across study areas [1]. This limitation becomes evident when surveying studies
25 that implement this type of analysis. For example, Páez et al. [44] (in Montreal)
26 and Campbell et al. [9] (in Nairobi) report accessibility as the number of health
27 care facilities that can potentially be reached from origins. But what does it
28 mean for a zone to have accessibility to less than 100 facilities in each of these
29 two cities, with their different populations and number of facilities? For that
30 matter, what does it mean for a zone to have accessibility to more than 700
31 facilities in Montreal, besides being “accessibility rich”? As another example,
32 Bocarejo S. and Oviedo H. [7] (in Bogota), El-Geneidy et al. [17] (in Montreal),
33 and Jiang and Levinson [27] (in Beijing) report accessibility as numbers of
34 jobs, with accessibility values often in the hundreds of thousands, and even
35 exceeding one million jobs for some zones in Beijing and Montreal. As indicators
36 of urban structure, these measures are informative, but the meaning of one
37 million accessible jobs is harder to pin down: how many jobs must any single
38 person have access to? Clearly, the answer to this question depends on how
39 many people demand jobs.

40 The interpretability of gravity-type accessibility has been discussed in nu-
41 merous studies, including recently by Hu and Downs [26], Kelobonye et al. [29],
42 and in greater depth by Merlin and Hu [35]. As hinted above, the limitations in
43 interpretability are frequently caused by ignoring competition - without com-
44 petition, each opportunity is assumed to be equally available to every single
45 opportunity-seeking individual that can reach it [50, 40, 29]. This assumption is
46 appropriate when the opportunity of interest is non-exclusive, that is, if use by
47 one unit of population does not preclude use by another. For instance, national
48 parks with abundant space are seldom used to full capacity, so the presence of

some population does not exclude use by others. When it comes to exclusive opportunities, or when operations may be affected by congestion, the solution has been to account for competition. Several efforts exist that do so. In our reckoning, the first such approach was proposed by Weibull [54], whereby the distance decay of the supply of employment and the demand for employment (by workers) were formulated under so-called axiomatic assumptions. This approach was then applied by Joseph and Bantock [28] in the context of healthcare, to quantify the availability of general practitioners in Canada. About two decades later, Shen [50] independently re-discovered Weibull’s [1976] formula [see footnote (7) in 50] and deconstructed it to consider accessibility for different modes. These advances were subsequently popularized as the family of two-step floating catchment area (2SFCA) methods [34] that have found widespread adoption in healthcare, education, and food systems [58, 13, 59, 12, 11].

An important development due to Shen was to show that the population-weighted sum of the accessibility measure with competition equates the number of opportunities available [footnote (7) and Appendix A in 50]. This demonstration gave the impression of a method that allocates all opportunities *exactly*. In this paper we intend to revisit accessibility with competition. We argue that Shen’s proof confuses the opportunity-seeking population with total zonal population, an equivocation that results in misleading allocations of opportunities to population that are masked by the presentation of results as rates (i.e., opportunities per capita). We then propose an alternative formulation of accessibility that incorporates competition by adopting a proportional allocation mechanism. The use of balancing factors for proportional allocation is akin to imposing a single constraint on the accessibility indicator, in the spirit of Wilson’s [1971] spatial interaction model.

In this way, the aim of the paper is three-fold:

- First, we aim to demonstrate that Shen-type (and thus Weibull [54] accessibility and the popular 2SFCA methods) produce misleading estimates of the opportunities allocated;
- Second, we introduce a new measure, *spatial availability*, which we submit is a more interpretable alternative to Shen-style accessibility, since opportunities in the system are preserved and proportionally allocated to the population; and
- Third, we show how Shen-type accessibility (and 2SFCA methods) can be seen as measures of singly-constrained accessibility.

Discussion is supported by the use of a small synthetic example drawn from Shen [50] and empirical data drawn from the 2016 Transportation Tomorrow Survey of the Greater Toronto and Hamilton Area in Ontario, Canada. In the spirit of openness of research in the spatial sciences [8, 43] this paper has a companion open data product [4], and all code is available for replicability and reproducibility purposes.

91 2. Accessability measures revisited

92 2.1. Hansen-type accessibility

93 Accessibility analysis stems from the foundational works of Harris [22] and
 94 Hansen [21]. From these seminal efforts, many accessibility measures (excluding
 95 utility-based measures) have been derived, particularly after the influential work
 96 of Wilson [56] on spatial interaction. The model follows the formulation shown
 97 in Equation (1):

$$S_i = \sum_{j=1}^J O_j \cdot f(c_{ij}) \quad (1)$$

98 where:

- 99 • S is Hansen-type accessibility.
- 100 • i is a set of origin locations.
- 101 • j is a set of destination locations.
- 102 • O_j is the number of opportunities at location j ; $\sum_j O_j$ is the total supply
 103 of opportunities in the study region.
- 104 • c_{ij} is a measure of the cost of moving between i and j .
- 105 • $f(\cdot)$ is an impedance function of c_{ij} ; it can take the form of any monotoni-
 106 cally decreasing function chosen based on positive or normative criteria
 107 [38].

108 As formally defined, accessibility S_i is the sum of opportunities that can
 109 be reached from location i , weighted down by an impedance function of the
 110 cost of travel c_{ij} . Summing the opportunities in the neighborhood of i provides
 111 estimates of the number of opportunities that can *potentially* be reached from
 112 i . Several variants of this method result from using a variety of impedance
 113 functions; for example, cumulative opportunities measures are obtained when
 114 $f(\cdot)$ is a binary or indicator function [e.g., 17, 48, 18, 45]. Other measures use
 115 impedance functions modeled after any monotonically decreasing function [e.g.,
 116 Gaussian, inverse power, negative exponential, or log-normal, among others,
 117 see, *inter alia*, 30, 52, 47, 32]. In practice, accessibility measures with different
 118 impedance functions tend to be highly correlated [23, 49, 30].

119 Gravity-based accessibility has been shown to be an excellent indicator
 120 of the intersection between urban structure and transportation infrastructure
 121 [51, 47, 30]. However, beyond enabling comparisons of relative values they are
 122 not highly interpretable on their own [36]. To address the issue of interpretability,
 123 previous research has aimed to index and normalize values on a per demand-
 124 population basis [e.g., 5, 41, 53]. However, as recent research on accessibility
 125 discusses [35, 1, 40, 29], these steps do not truly adequately consider competition.
 126 In effect, when calculating S_i , every opportunity enters the weighted sum once
 127 for every origin i that can reach it. This makes interpretability opaque, and to
 128 complicate matters, can also bias the estimated landscape of opportunity.

129 *2.2. Shen-type competitive accessibility*

130 To account for competition, the influential works of Shen [50] and Weibull
 131 [54], as well as the widely used 2SFCA approach of Luo and Wang [34], adjust
 132 Hansen-type accessibility with the population in the region of interest. The
 133 mechanics of this approach consist of calculating, for every destination j , the
 134 population that can reach it given the impedance function $f(\cdot)$. Shen [50]
 135 calls this “the opportunity-seeking population”. The opportunities at j are
 136 then divided by their corresponding opportunity-seeking population to obtain a
 137 measure of opportunities per capita, i.e., R_j in Equation (2). Per capita values
 138 are then allocated back to the population at i , again subject to the impedance
 139 function. Equation (2) corresponds to the first step of this procedure, and
 140 Equation (3) to the second.

$$R_j = \frac{O_j}{\sum_i P_i \cdot f(c_{ij})} \quad (2)$$

$$A_i = \sum_j R_j \cdot f(c_{ij}) \quad (3)$$

141 where:

- 142 • A is Shen-type accessibility.
- 143 • i is a set of origin locations.
- 144 • j is a set of destination locations.
- 145 • O_j is the number of opportunities at location j ;
- 146 • P_i is the population at location i ; $\sum_j R_j$ is the total supply of opportunities
 147 in the study region.
- 148 • R_j is the provider-to-population (PPR) ratio at location j ;
- 149 • c_{ij} is a measure of the cost of moving between i and j ;
- 150 • $f(\cdot)$ is an impedance function of c_{ij} .

151 As noted above, Shen [50] furnished a demonstration that the resulting values
 152 of A_i , when multiplied by the population at that origin and summed for the full
 153 study region, equates the total number of opportunities in the full study region.
 154 But is this really the case?

155 *2.3. Example*

156 To motivate the discussion, we begin with the example in Shen [50]. This is
 157 the simple system shown in Figure 1.

158 Table 1 contains the information needed to calculate S_i and A_i for this
 159 example. In the table we see that population centers A and B have equal
 160 Hansen-type accessibility ($S_A = S_B = 27,292$ jobs), despite A having a much
 161 smaller population. On the other hand, the isolated satellite town of C has
 162 low accessibility ($S_C = 2,240$ jobs). This value is not very sensible: given its
 163 isolated position in the system and balanced jobs-population ratio, it would be
 164 more natural if it had better accessibility than B , with its large population and

Figure 1: Shen (1998) synthetic example with locations of employment centers (in orange), population centers (in blue), number of jobs and population, and travel times.

distance to jobs. It is difficult from these outputs to determine whether the accessibility at B is better or worse than that at A or C .

The results are much easier to interpret when we consider Shen-type accessibility. The results indicate that $A_A \approx 1.337$ jobs per capita, $A_B \approx 0.888$, and $A_C \approx 0.996$. The latter value is sensible given the job-population balance of C . Center A is relatively close to a large number of jobs (more jobs than the population of A). The opposite is true of B . According to Shen [50], the sum of the population-weighted accessibility A_i is exactly equal to the number of jobs in the region:

$$\begin{aligned}
 &50,000 \times 1.3366693 \\
 &+150,000 \times 0.8880224 \\
 &+10,000 \times 0.9963171 = 210,000
 \end{aligned}$$

As mentioned in the introduction, this property gives the impression that jobs are allocated in their totality. However, for this property to work, the accessibility needs to be multiplied by the total population of the corresponding center. Alas, there is a logical inconsistency in this calculation, since the travel behavior, encoded in the form of the impedance function, means that the opportunity-seeking population is *not* equal to the total population. In other words, the total population is confounded with the *opportunity-seeking population*. As seen in column **Pop * f(TT)** in Table 1, the number of individuals from population center A that are *willing to reach* employment centers 1, 2, and 3 are 11,156, 2,489, and 2.27 respectively. Therefore, the total number of opportunity-seeking individuals is 13,647.27, which is considerably lower than the total population of A .

Table 1: Summary description of synthetic example: Hansen-type accessibility and Shen-type accessibility with competition

Origin	Pop.	Dest.	Jobs	TT	f(TT)	Pop * f(TT)	Jobs * f(TT)	S_i	A_i
A	50,000	1	100,000	15	0.223130	11,157	22,313	27,292	1.34
		2	100,000	30	0.049787	2,489	4,979		
		3	10,000	100	0.000045	2.27	0.454		
B	150,000	1	100,000	30	0.049787	7,468	4,979	27,292	0.888
		2	100,000	15	0.223130	33,470	22,313		
		3	10,000	100	0.000045	6.81	0.454		
C	10,000	1	100,000	100	0.000045	0.454	4.54	2,240	0.996
		2	100,000	100	0.000045	0.454	4.54		
		3	10,000	15	0.223130	2,231	2,231		

To ensure that the calculations are consistent with the travel behavior given by the impedance function, the number of accessible jobs per capita should be multiplied by the population who are willing to travel to the employment center; hence, instead of the nominal number of jobs in the region, the number of jobs the method actually allocates is:

$$\begin{aligned}
& (11,156.51 + 2,489.35 + 2.26) \times 1.3366693 \\
& + (7,468.06 + 33,469.52 + 6.81) \times 0.8880224 \\
& + (4.54 + 4.54 + 2,231.20) \times 0.9963171 \approx 56,834.59
\end{aligned}$$

179 which is just a proportion of the total number of jobs in the region. Use of
180 the total population of zones when calculating the population-weighted sum
181 of A_i gives the impression that all jobs are allocated - however the result is
182 inconsistent with the travel behavior embedded in the model. When the correct
183 opportunity-seeking population is used (that is, the population weighted by the
184 impedance), it becomes apparent that the number of jobs allocated is not equal
185 to the total number of jobs in the region. This feature of the method is masked
186 because the results are given in terms of opportunities per capita. This result
187 raises suspicions, because it indicates seldom-seen levels of unemployment and
188 job vacancies, despite the seemingly-reasonable values of A_i . In the next section
189 we propose an alternative derivation of competitive accessibility that resolves
190 the apparent inconsistency described in this section.

191 **3. Introducing spatial availability: a singly-constrained accessibility** 192 **measure**

193 In brief, we define the *spatial availability* at i (V_i) as the proportion of all
194 opportunities O that are allocated to i from all destinations j . The fundamental
195 difference with Hansen- and Shen-type accessibility is that opportunities are
196 allocated proportionally. We begin by explaining the intuition behind the method
197 before defining it more formally.

198 *3.1. Proportional allocation by population*

According to the gravity modelling framework, the potential for interaction depends on the mass (i.e., the population) and the friction of distance (i.e., the impedance function). We begin by describing the proposed proportional allocation mechanism based on demand by population. The total population in the example is 210,000. The proportion of the population by population center is:

$$\begin{aligned} F_A^p &= \frac{50,000}{210,000} \\ F_B^p &= \frac{150,000}{210,000} \\ F_C^p &= \frac{10,000}{210,000} \end{aligned}$$

199 Jobs are allocated proportionally from each employment center to each population
200 center depending on their population sizes as per the balancing factors F_i^p . In
201 this way, employment center 1 allocates $100,000 \cdot \frac{50,000}{210,000} = 23,809.52$ jobs to
202 A ; $100,000 \cdot \frac{150,000}{210,000} = 71,428.57$ jobs to B ; and $100,000 \cdot \frac{10,000}{210,000} = 7,142.857$
203 jobs to C . Notice how this mechanism ensures that the total number of jobs at
204 employment center 1 is preserved at 100,000.

We can verify that the number of jobs allocated is consistent with the total number of jobs in the region:

$$\begin{aligned} &\text{Employment center 1 to population centers A, B, and C:} \\ &100,000 \cdot \frac{50,000}{210,000} + 100,000 \cdot \frac{150,000}{210,000} + 100,000 \cdot \frac{10,000}{210,000} = 100,000 \\ &\text{Employment center 2 to population centers A, B, and C:} \\ &100,000 \cdot \frac{50,000}{210,000} + 100,000 \cdot \frac{150,000}{210,000} + 100,000 \cdot \frac{10,000}{210,000} = 100,000 \\ &\text{Employment center 3 to population centers A, B, and C:} \\ &10,000 \cdot \frac{50,000}{210,000} + 10,000 \cdot \frac{150,000}{210,000} + 10,000 \cdot \frac{10,000}{210,000} = 10,000 \end{aligned}$$

205 In the general case where there are N population centers in the region, we
206 define the following population-based balancing factors:

$$F_i^p = \frac{P_i^\alpha}{\sum_{i=1}^N P_i^\alpha} \quad (4)$$

207 Balancing factor F_i^p corresponds to the proportion of the population in
208 origin i relative to the population in the region. On the right hand side of the
209 equation, the numerator P_i^α is the population at origin i . The summation in the
210 denominator is over $i = 1, \dots, N$, and adds up to the total population of the
211 region. Notice that we incorporate an empirical parameter α . The role of α is

212 to modulate the effect of demand by population. When $\alpha < 1$, opportunities are
 213 allocated more rapidly to smaller centers relative to larger ones; $\alpha > 1$ achieves
 214 the opposite effect.

Balancing factor F_i^p can now be used to proportionally allocate a share of available jobs at j to origin i . The number of jobs available to i from j balance by population shares is defined as follows:

$$V_{ij}^p = O_j \frac{F_i^p}{\sum_{i=1}^K F_i^p}$$

In the general case when there are J employment centers, the total number of jobs available from all destinations is simply the sum of V_{ij}^p over $j = 1, \dots, J$:

$$V_i^p = \sum_{j=1}^J O_j \frac{F_i^p}{\sum_{i=1}^K F_i^p}$$

Since factors F_i^p summed over $i = 1, \dots, N$ always equals to 1 (i.e., $\sum_{i=1}^N F_i^p = 1$), the sum of all spatially available jobs equals O , the total number of opportunities in the region:

$$\begin{aligned} \sum_{i=1}^N V_i^p &= \sum_{i=1}^N \sum_{j=1}^J O_j \frac{F_i^p}{\sum_{i=1}^N F_i^p} \\ &= \sum_{i=1}^N \frac{F_i^p}{\sum_{i=1}^N F_i^p} \cdot \sum_{j=1}^J O_j \\ &= \sum_{j=1}^J O_j = O \end{aligned}$$

215 The terms F_i^p act here as the balancing factors of the gravity model when a
 216 single constraint is imposed [i.e., to ensure that the sums of columns are equal
 217 to the number of opportunities per destination, see 37, pp. 179-180 and 183-184].
 218 As a result, the sum of spatial availability for all population centers equals the
 219 total number of opportunities.

220 The discussion so far concerns only the mass effect (i.e., population size)
 221 of the gravity model. In addition, the potential for interaction is thought to
 222 decrease with increasing cost, so next we define similar balancing factors but
 223 based on the impedance.

224 3.2. Proportional allocation by cost

Clearly, using only balancing factors F_i^p to calculate spatial availability V_i^p does not account for the cost of reaching employment centers. Consider instead a set of balancing factors F_{ij}^c that account for the friction of distance:

$$\begin{aligned} F_{A1}^c &= \frac{0.223130}{0.223130+0.049787+0.000045} = 0.8174398 \\ F_{B1}^c &= \frac{0.049787}{0.223130+0.049787+0.000045} = 0.1823954 \\ F_{C1}^c &= \frac{0.000045}{0.223130+0.049787+0.000045} = 0.0001648581 \end{aligned}$$

225 Balancing factors F_{ij}^c use the impedance function to proportionally allocate
 226 more jobs to closer population centers, that is, those with populations *more*

227 *willing to reach the jobs.* Indeed, the factors F_{ij}^c can be thought of as the
 228 proportion of the population at i willing to travel to destination j conditional
 229 on the travel behavior as given by the impedance function.

230 In our example, the number of jobs allocated from employment center 1 to
 231 population center A is $100,000 \times 0.8174398 = 81743.98$; to population center B
 232 is $100,000 \times 0.1823954 = 18,239.54$; and to population center C is $100,000 \times$
 233 $0.0001648581 = 16.48581$. We can see once more that the total number of jobs at
 234 the employment center is preserved at 100,000. In this example, the proportional
 235 allocation mechanism assigns the largest share of jobs to population center A ,
 236 which is the closest to employment center 1, and the smallest to the more distant
 237 population center C .

238 In the general case when there are N population centers and J employment
 239 centers in the region, we define the following cost-based balancing factors:

$$F_{ij}^c = \frac{f(c_{ij})}{\sum_{i=1}^N f(c_{ij})} \quad (5)$$

The total number of jobs available to i from j according to cost is defined as follows:

$$V_{ij}^c = O_j \frac{F_i^c}{\sum_{i=1}^N F_i^c}$$

The total number of jobs available to i from all destinations is:

$$V_i^c = \sum_{j=1}^J O_j \frac{F_i^c}{\sum_{i=1}^N F_i^c}$$

Like the population-based allocation factors, F_i^c summed over $i = 1, \dots, N$ always equals to 1 (i.e., $\sum_{i=1}^N F_i^c = 1$). As before, the sum of all spatially available jobs equals O , the total number of opportunities in the region:

$$\begin{aligned} \sum_{i=1}^N V_i^c &= \sum_{i=1}^N \sum_{j=1}^J O_j \frac{F_i^c}{\sum_{i=1}^N F_i^c} \\ &= \sum_{i=1}^N \frac{F_i^c}{\sum_{i=1}^N F_i^c} \cdot \sum_{j=1}^J O_j \\ &= \sum_{j=1}^J O_j = O \end{aligned}$$

240 We are now ready to more formally define spatial availability with due
 241 consideration to both mass and cost effects.

242 3.3. Putting spatial availability together

243 Population and the cost of travel are both part of the gravity modelling
 244 framework. Since the balancing factors defined in the preceding sections are
 245 proportions (alternatively probabilities), they can be combined multiplicatively
 246 to obtain their joint effect (alternatively, the joint probability of allocating
 247 opportunities). This idea is captured by Equation (6), where F_i^p is a population-
 248 based allocation factor that grants a larger share of the existing opportunities
 249 to larger centers, and F_{ij}^c is a transportation cost-based allocation factor that

250 grants a larger share of the existing opportunities to closer centers. This is in
 251 line with the tradition of gravity modeling.

$$F_i^t = \frac{F_i^p \cdot F_{ij}^c}{\sum_{i=1}^N F_i^p \cdot F_{ij}^c} \quad (6)$$

252 Balancing factors F_i^t are used to proportionally allocate jobs from j to i . The
 253 spatial availability is given by Equation (7).

$$V_i = \sum_{j=1}^J O_j \frac{F_i^t}{\sum_{i=1}^N F_i^t} \quad (7)$$

254 The terms in Equation 7 are as follows:

- 255 • V_i is the spatial availability at i .
- 256 • i is a set of origin locations in the region $i = 1, \dots, N$.
- 257 • j is a set of destination locations in the region $j = 1, \dots, J$.
- 258 • O_j is the number of opportunities at location j .
- 259 • F_i^t is a balancing factor as defined in Equation (6).

260 Notice that, unlike S_i in Equation (1), the population enters the calculation
 261 of V_i . Returning to the example in Figure 1, Table 2 contains the information
 262 needed to calculate V_i .

Table 2: Summary description of synthetic example: spatial availability

Origin	Pop.	Dest.	Jobs	TT	f(TT)	F ^p	F ^c	F	V _{ij}	V _i
A	50,000	1	100,000	15	0.223130	0.238095	0.817438	0.599006	59,901	66,833
		2	100,000	30	0.049787	0.238095	0.182395	0.069227	6,923

In the table, column **V_{ij}** are the jobs available to each origin from each employment center. In this column $V_{A1} = 59,901$ is the number of jobs available at A from employment center 1. Column **V_i** (i.e., $\sum_{j=1}^J V_{ij}$) gives the total

number of jobs available to origin i . We can verify that the total number of jobs available is consistent with the total number of jobs in the region (with some small rounding error):

$$\sum_{i=1}^N V_i = 66,833 + 133,203 + 9,963 \approx 210,000$$

263 Compare the calculated values of V_i to column **S_i** (Hansen-type accessi-
 264 bility) in Table 1. The spatial availability values are more intuitive. Recall
 265 that population centers A and B had identical Hansen-type accessibility to
 266 employment opportunities. According to V_i , population center A has greater job
 267 availability due to its close proximity to employment center 1 combined with
 268 less steep competition (i.e., a majority of the population have to travel longer
 269 distances to reach employment center 1). Job availability is lower for population
 270 center B due to much higher competition (150,000 people can reach 100,000
 271 jobs at equal cost). And center C has almost as many jobs available as it has
 272 population.

273 As discussed above, Hansen-type accessibility is not designed to preserve the
 274 number of jobs in the region. Shen-type accessibility is internally inconsistent:
 275 the only way it preserves the number of jobs is if the effect of the impedance
 276 function is ignored when expanding the values of jobs per capita to obtain the
 277 total number of opportunities. The proportional allocation procedure described
 278 above, in contrast, consistently returns a number of jobs available that matches
 279 the total number of jobs in the region.

280 Since the jobs spatially available are consistent with the jobs in the region, it
 281 is possible to define a measure of spatial availability per capita:

$$v_i = \frac{V_i}{P_i} \quad (8)$$

282 And, since the jobs are preserved, it is possible to use the regional jobs per
 283 capita as a benchmark to compare the spatial availability of jobs per capita at
 284 each origin:

$$\frac{\sum_{j=1}^J O_j}{\sum_{i=1}^N P_i} \quad (9)$$

285 In the example, since the population is equal to the number of jobs, the
 286 regional value of jobs per capita is 1.0. To complete the illustrative example, the
 287 spatial availability of jobs per capita by origin is:

$$\begin{aligned} v_1 &= \frac{V_1}{P_1} = \frac{66,833.47}{50,000} = 1.337 \\ v_2 &= \frac{V_2}{P_2} = \frac{133,203.4}{150,000} = 0.888 \\ v_3 &= \frac{V_3}{P_3} = \frac{9,963.171}{10,000} = 0.996 \end{aligned} \quad (10)$$

288 We can see that population center A has fewer jobs per capita than the
 289 regional benchmark, center B has more, and center C is at parity. Remarkably,

the spatial availability per capita matches the values of A_i in Table 1. Appendix A has a proof of the mathematical equivalence between the two measures. It is interesting to notice how Weibull [54], Shen [50], as well as this paper, all reach identical expressions starting from different assumptions; this effect is known as *equifinality* [see 37, p. 333; and 55]. Interestingly, this result means that Shen-type accessibility and 2SFCA can be conceptualized as singly-constrained accessibility measures.

3.4. Why does proportional allocation matter?

Having shown that Shen-type accessibility and spatial availability produce equifinal results, it is reasonable to ask whether the distinction between them is of any import.

Conceptually, we would argue that the internal inconsistency in the calculation of total opportunities in Shen [50] points at a more serious problem that is only evident when we consider the internal values of the method. To illustrate, Table 1 shows results of A_i that are reasonable (in fact, they match exactly the spatial availability per capita). But when we dig deeper, these results mask potentially misleading values of jobs allocated and taken. In addition, the internal values also lead to estimates of the impact of accessibility that are deceptive. For example, the estimated system-wide cost of travel considering the jobs allocated by A_i in Table 1 is as follows:

$$\begin{aligned} &11,157 \times 15 \text{ min} + 2,489 \times 30 \text{ min} + 2.27 \times 100 \text{ min} \\ &7,468 \times 30 \text{ min} + 33,470 \times 15 \text{ min} + 6.81 \times 100 \text{ min} \\ &0.454 \times 100 \text{ min} + 0.454 \times 100 \text{ min} + 2,231 \times 15 \text{ min} = 1,002,581 \text{ min} \end{aligned}$$

In contrast, the estimated system-wide cost of travel according to V_i in Table 2 is as follows:

$$\begin{aligned} &59,901 \times 15 \text{ min} + 6,923 \times 30 \text{ min} + 10 \times 100 \text{ min} \\ &40,097 \times 30 \text{ min} + 93,076 \times 15 \text{ min} + 30 \times 100 \text{ min} \\ &2.4 \times 100 \text{ min} + 1.3 \times 100 \text{ min} + 9,959 \times 15 \text{ min} = 3,859,054 \text{ min} \end{aligned}$$

Therefore, not only does the Shen-type measure effectively allocate fewer than 56,835 out of a total of 210,000 jobs in the region, it also grossly underestimates the potential cost of travel in the system by obscuring the number of jobs not allocated.

4. Empirical example of Toronto

In this section we illustrate the application of spatial availability through an empirical example. For this, we use population and employment data from the Greater Toronto and Hamilton Area (GTHA) in Ontario, Canada. This is the largest metropolitan region in Canada. We calculate gravity accessibility, XXX, and the proposed spatial availability for Toronto after introducing the data used and calibrating an impedance function.

312 4.1. Data

313 We obtained population and employment data from the 2016 Transporta-
 314 tion Tomorrow Survey (TTS). This survey collects representative urban travel
 315 information from 20 municipalities contained within the GTHA area in the
 316 southern part of Ontario, Canada (see Figure 2) [14]. The data set includes
 317 Traffic Analysis Zones (TAZ) (n=3,764), the number of jobs (n=3,081,885) and
 318 workers (n=3,446,957) at each origin and destination. The TTS data is based on
 319 a representative sample of between 3% to 5% of households in the GTHA and is
 320 weighted to reflect the population covering the study area has a whole [14].

321 To generate the travel cost for these trips, travel times between origins and
 322 destinations are calculated for car travel using the R package {r5r} [46] with a
 323 street network retrieved from OpenStreetMap. For the calculations a 3 hr travel
 324 time threshold was selected as it captures 99% of population-employment pairs
 325 (see the travel times summarized in Figure 2). This method does not account for
 326 traffic congestion or modal split, which can be estimated through other means
 327 [e.g., 2, 24]. For simplicity, we carry on with the assumption that all trips are
 328 taken by car in uncongested travel conditions. All data and data preparation
 329 steps are documented and can be freely explored in the companion open data
 330 product {TTS2016R}.

331 4.2. Calibration of an impedance function

332 In the synthetic example introduced in a preceding section, we used a negative
 333 exponential function with the parameter reported by Shen [50]. For the empirical
 334 example, we calibrate an impedance function on the trip length distribution
 335 (TLD) of commute trips. Briefly, a TLD represents the proportion of trips that
 336 are taken at a specific travel cost (e.g., travel time); this distribution is commonly
 337 used to derive impedance functions in accessibility research [33, 25, 6].

338 The empirical and theoretical TLD for this data set are represented in the
 339 top-left panel of Figure 3. Maximum likelihood estimation and the Nelder-
 340 Mead method for direct optimization available within the {fitdistrplus} package
 341 [16] were used. Based on goodness-of-fit criteria and diagnostics the gamma
 342 distribution was selected (see Figure 3).

343 The gamma distribution is defined in Equation (11), where we see that it
 344 depends on a shape parameter α and a rate parameter β . The estimated values
 345 of these parameters are $\alpha = 2.019$ and $\beta = 0.094$.

$$\begin{aligned} f(x, \alpha, \beta) &= \frac{x^{\alpha-1} e^{-\frac{x}{\beta}}}{\beta^{\alpha} \Gamma(\alpha)} \quad \text{for } 0 \leq x \leq \infty \\ \Gamma(\alpha) &= \int_0^{\infty} x^{\alpha-1} e^{-x} dx \end{aligned} \quad (11)$$

Figure 2: TTS 2016 study area (GGH, Ontario, Canada) along with the descriptive statistics of the trips, calculated origin-destination car travel time (TT), workers per TAZ, and jobs per TAZ. Contains 20 regions (black boundaries) and sub-regions (dark gray boundaries).

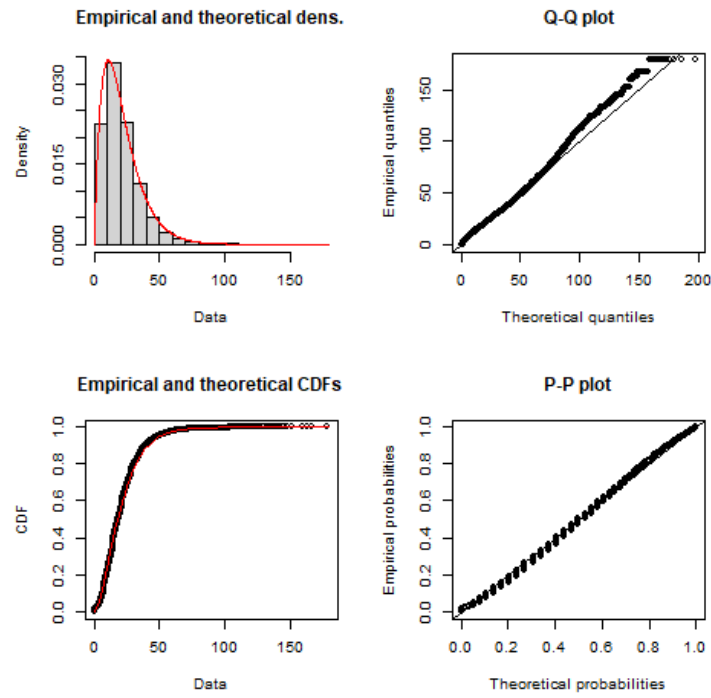

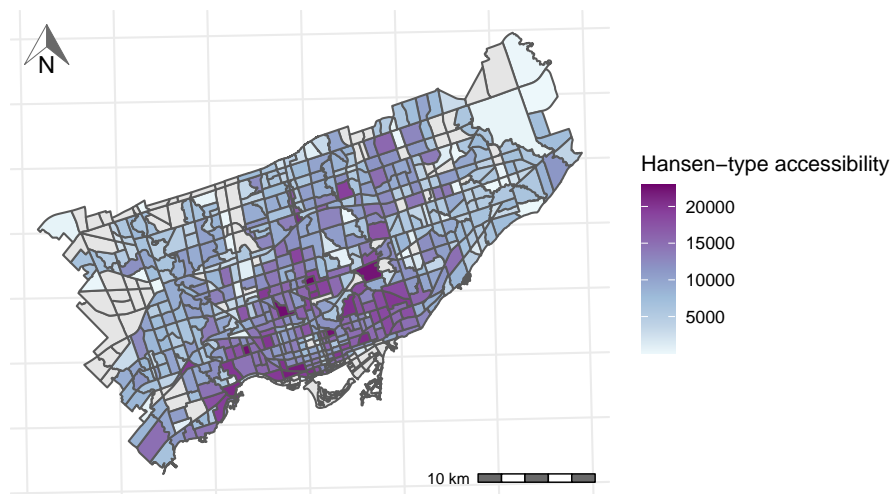

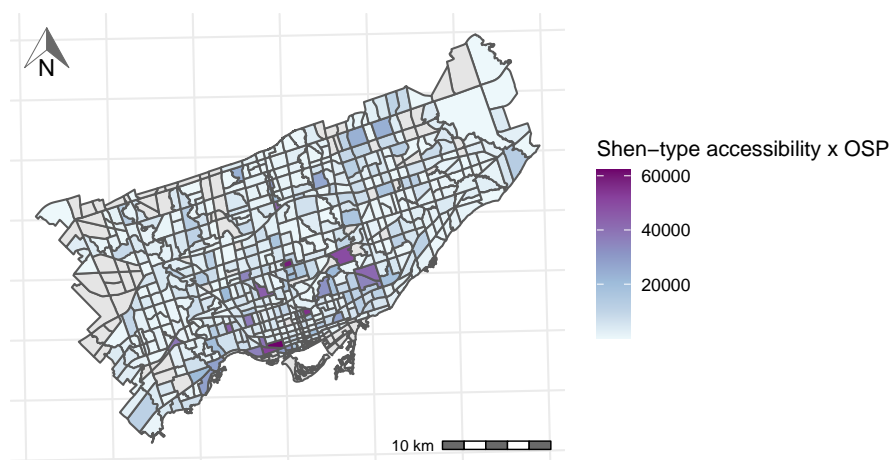

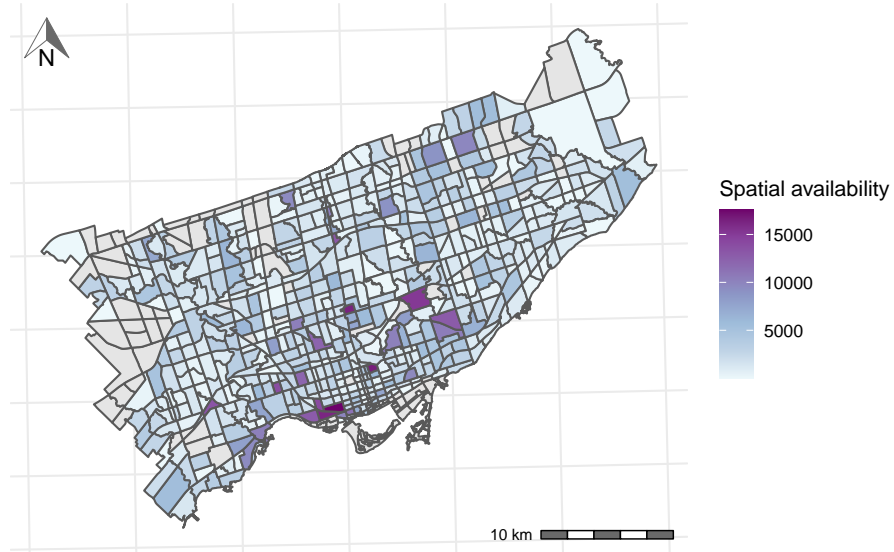

Figure 3: Car trip length distribution and calibrated gamma distribution impedance function (red line) with associated Q-Q and P-P plots. Based on TTS 2016.

346

347

348

349 *4.3. Accessibility and spatial availability of jobs in Toronto*

350 Toronto is the largest city in the GGH and represents a significant subset
 351 of workers and jobs in the GGH; 31% of workers in the GGH travel to jobs in
 352 Toronto and 40% of jobs are located within Toronto.

5. Discussion and Conclusions

Words go here.

6. Appendix A

Equivalence of Shen-type accessibility and spatial availability

Population allocation factor:

$$F_{ij}^p = \frac{P_{i \in r}^\alpha}{\sum_i^K \frac{P_A^\alpha}{P_{i \in r}^\alpha}}$$

$$F_A^p = \frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha}$$

Cost allocation factor:

$$F_{ij}^c = \frac{f(c_{ij})}{\sum_{i=A}^K f(c_{ij})}$$

$$F_{A1}^c = \frac{f(c_{A1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})} \quad F_{B1}^c = \frac{f(c_{A2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})} \quad F_{C1}^c = \frac{f(c_{A3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})}$$

Now let's put it together with P, and see how the denominators end up

cancelling out:

$$v_i = \sum_j \frac{O_j}{P_{i \in r}^\alpha} \frac{\sum_i^K \frac{P_{i \in r}^\alpha}{\sum_i^K \frac{P_A^\alpha}{P_{i \in r}^\alpha}} \cdot \frac{f(c_{ij})}{\sum_i^K f(c_{ij})}}{\sum_i^K \frac{P_{i \in r}^\alpha}{\sum_i^K \frac{P_A^\alpha}{P_{i \in r}^\alpha}} \cdot \frac{f(c_{ij})}{\sum_i^K f(c_{ij})}}$$

$$v_A = \frac{O_1}{P_A^\alpha} \left(\frac{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})}}{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})} + \frac{P_B^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{B1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})} + \frac{P_C^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{C1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})}} \right) +$$

$$\frac{O_2}{P_A^\alpha} \left(\frac{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})}}{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})} + \frac{P_B^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{B2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})} + \frac{P_C^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{C2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})}} \right) +$$

$$\frac{O_3}{P_A^\alpha} \left(\frac{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})}}{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})} + \frac{P_B^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{B3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})} + \frac{P_C^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{C3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})}} \right)$$

First, notice how the denominator on the denominator is the same across the

summation? Let's simplify it:

$$v_A = \frac{O_1}{P_A^\alpha} \left(\frac{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})}}{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})} + \frac{P_B^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{B1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})} + \frac{P_C^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{C1})}{f(c_{A1})+f(c_{B1})+f(c_{C1})}} \right) +$$

$$\frac{O_2}{P_A^\alpha} \left(\frac{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})}}{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})} + \frac{P_B^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{B2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})} + \frac{P_C^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{C2})}{f(c_{A2})+f(c_{B2})+f(c_{C2})}} \right) +$$

$$\frac{O_3}{P_A^\alpha} \left(\frac{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})}}{\frac{P_A^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{A3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})} + \frac{P_B^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{B3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})} + \frac{P_C^\alpha}{P_A^\alpha + P_B^\alpha + P_C^\alpha} \cdot \frac{f(c_{C3})}{f(c_{A3})+f(c_{B3})+f(c_{C3})}} \right)$$

See how the denominator of the denominator is the same as the denominator of the numerator's denominator for each J (J=1, J=2, and J=3)? Let's cancel those out and simplify:

$$v_A = \frac{O_1}{P_A^\alpha} \left(\frac{P_A^\alpha \cdot f(c_{A1})}{P_A^\alpha \cdot f(c_{A1}) + P_B^\alpha \cdot f(c_{B1}) + P_C^\alpha \cdot f(c_{C1})} \right) + \frac{O_2}{P_A^\alpha} \left(\frac{P_A^\alpha \cdot f(c_{A2})}{P_A^\alpha \cdot f(c_{A2}) + P_B^\alpha \cdot f(c_{B2}) + P_C^\alpha \cdot f(c_{C2})} \right) +$$

$$\frac{O_3}{P_A^\alpha} \left(\frac{P_A^\alpha \cdot f(c_{A3})}{P_A^\alpha \cdot f(c_{A3}) + P_B^\alpha \cdot f(c_{B3}) + P_C^\alpha \cdot f(c_{C3})} \right)$$

Next, see how we can cancel out the P_A^α ? Let's do that.

$$v_A = O_1 \left(\frac{f(c_{A1})}{P_A^\alpha \cdot f(c_{A1}) + P_B^\alpha \cdot f(c_{B1}) + P_C^\alpha \cdot f(c_{C1})} \right) + O_2 \left(\frac{f(c_{A2})}{P_A^\alpha \cdot f(c_{A2}) + P_B^\alpha \cdot f(c_{B2}) + P_C^\alpha \cdot f(c_{C2})} \right) +$$

$$O_3 \left(\frac{f(c_{A3})}{P_A^\alpha \cdot f(c_{A3}) + P_B^\alpha \cdot f(c_{B3}) + P_C^\alpha \cdot f(c_{C3})} \right)$$
